Abstract

Seawater desalination is vital to our modern civilization. Here, we report that the carbon honeycomb (CHC) has an outstanding water permeability and salt rejection in the seawater desalination, as revealed by molecular dynamics simulations. More than 92% of ions are rejected by CHC at applied pressures ranging from 50 to 250 MPa. CHC has a perfect salt rejection at pressures below 150 MPa. On increasing the applied pressure up to 150 MPa, the salt rejection reduces only to 92%. Pressure, temperature and temperature gradient are noted to play a significant role in modulating the water flux. The water flux increases with pressure and temperature. With the introduction of a temperature gradient of 3.5 K/nm, the seawater permeability increases by 33% as compared to room temperature. The water permeability of the carbon honeycomb is greater than other carbon materials and osmosis membranes including graphene (8.7 times) and graphyne (2.1 times). It indicates the significant potential of the carbon honeycomb for commercial application in water purification.

Keywords: Carbon honeycomb; Desalination; Molecular dynamics simulation; Temperature gradient

1. Introduction

The production of fresh water is a significant challenge for the increasing population in the society [1]. Seawater desalination is vital to sustain the modern civilization of human beings as one of the most important sources for obtaining fresh water from the oceans and brackish reservoirs [2]. The reverse osmosis technology, which uses the pressure difference as a driving force to filter impurities, accounts for nearly half of the extent of water obtained from desalination [3], where the osmosis membranes play a crucial part, however, still suffer from instability and low efficiency.

The reverse osmosis membranes play an essential role in osmosis desalination and need to exhibit optimal stability, high water permeability and salt rejection for large-scale applications. Currently, commercial reverse osmosis membranes are widely used for salt rejection, however, the low water permeability (about $1 \text{ L}/(\text{m}^2 \cdot \text{h} \cdot \text{Bar})$) and high capital costs have limited the development of such commercial membranes for water treatment [4]. Moreover, the conventional reverse osmosis membranes degrade in the presence of chlorine and are easily fouled by the organic matter [5]. In this respect, many research efforts have been made to develop new nanoporous membrane materials with much higher stability and effective water desalination performance.

Carbon is known to be a flexible element with high stability. It can take form of various allotropes, such as carbon nanotubes (CNT), graphene and graphyne, with a varying arrangement of atoms. Recently, CNT [6-8], graphyne [9] and graphene [10, 11] have been extensively studied for water desalination using both experiments and simulations. In particular, the experimental studies have shown that the porous CNT membranes have a water permeability and salt rejection much higher than the currently used commercial membranes [6], and the water flux increases with decreasing the membrane thickness [8]. Similarly, graphyne membranes have been widely investigated

1
2
3 as porous carbon nanomaterial for desalination, and the results show that water can
4 permeate swiftly through graphyne with high salt rejection [9]. Recently, nanopores have
5 been introduced into graphene's structure. Graphene can also be introduced into a variety
6 of chemically functionalized nanopores (for example, MoS₂ functionalized, hydroxylated
7 and hydrogenated pores) and has been demonstrated to exhibit several orders of
8 magnitude higher water permeability [10-13]. With high water permeability and salt
9 rejection, porous carbon nanomaterials have a high potential of commercial applications.

13
14
15
16
17
18
19 Pressure gradient is commonly used to generate controlled water flow in the
20 nanoscale desalination membranes [2]. In addition, the introduction of temperature
21 gradient has been proved to induce water flow in the nanoscale porous nanomaterials.
22 Harvey et al. [14] studied the translation motion of the water nanodroplets driven by the
23 temperature gradient in CNT. It was reported that the water flow imposed by the
24 temperature gradient could be controlled [15]. The thermo-diffusion caused by the
25 temperature gradient is known as the Soret effect or thermophoresis [16, 17].

33
34
35 Carbon honeycomb (CHC), a new kind of nanoporous carbon nanomaterials, has
36 been proposed by Park et al. [18]. The special honeycomb-like structure of CHC has
37 attracted a significant research attention since then. The sp²-sp³ hybridized CHC was
38 reported to have an outstanding stability with relatively small density and high specific
39 surface per unit volume [19]. Krainyukova et al. [20] experimentally developed stable
40 CHC for the first time. Since then, the structure and properties of CHC have been widely
41 explored [21]. CHC has excellent performance in liquid storage [20], along with
42 enhancement of thermal conductivity [22], electrical conductivity [23] and mechanical
43 properties [24-26]. For example, it was reported that the thermal conductivity of CHC in
44 the cell axis direction was up to 100 W/mK with a density as low as 0.4 g/cm³, and the
45 specific strength was higher than the other carbon materials [24].

1
2
3 The aforementioned unique properties might be attributed to the distinctive structure:
4
5 CHC essentially constitutes the rows of honeycomb holes. Rationally, it motivates the
6
7 research community to further explore its properties and applications in desalination.
8
9 Herein, a CHC with sp^2 bonding in the wall and sp^3 bonding in the junction has been
10
11 constructed, and the water desalination performance as a function of applied hydrostatic
12
13 pressure and length have been investigated using the non-equilibrium molecular
14
15 dynamics (NEMD) simulations. The effect of temperature and temperature gradient has
16
17 also been investigated.
18
19
20
21
22

23 2. Models and Methods

24
25 Tilted view of CHC is shown in [Figure 1\(a\)](#). As a kind of asymmetrical armchair
26
27 sp^2 - sp^3 bonded carbon honeycomb [\[27\]](#), it consists of graphene nanoribbons. The cross-
28
29 section is a honeycomb-like structure based on a regular hexagon with side length of 5.8
30
31 Å. Each CHC unit consists of four pores ([Figure 1\(b\)](#)) with periodic boundary conditions
32
33 in both x and y directions. The junction consists of an 8-carbon and two 5-carbon atom
34
35 rings (as shown in [Figure 1\(c\)](#)).
36
37
38

39
40 The water desalination system is composed of two graphene sheets as rigid piston at
41
42 the two ends of the simulation system along the z-axis, a CHC, salt water in the feed side
43
44 and fresh water in the permeate side ([Figure 1 \(d\)](#)). According to Robert S. Weatherup
45
46 [\[28\]](#), water will not escape from graphene and penetrate into the vacuum. The saltwater
47
48 in the feed side consists of 12 Na ions, 12 Cl ions and 1200 water molecules ($20 \times 17 \times 104$
49
50 Å.). This, thus, produces a salt water area with salinity of $32 \text{ g} \cdot \text{L}^{-1}$, which is close to the
51
52 salinity of seawater. Fresh water contains 300 water molecules with a size of $20 \times 17 \times 26$
53
54 Å. Besides, period boundary conditions are used in all directions, along with two 35 Å
55
56 vacuum layers placed at the two ends of the graphene piston so that no interaction occurs
57
58
59
60

between the left and right pistons. Therefore, with the length of CHC as 5.8 nm, the size of the simulation box is about $20 \times 17 \times 258$ Å. As the size of the simulation box becomes larger, it has a little effect on the obtained results. We studied the water flux by periodically replicating both x and y directions three times at 50 MPa. This way, the simulation box was enlarged by nine times. The difference in the water flux between the enlarged structure and pristine one is within 5%, implying that the result with such a simulation box is converged and independent of system size. In order to express the system structure more clearly, the simulation system with only 5.8 nm CHC has been shown in **Figure 1d**. The different lengths of CHC are shown in **Supplementary Figure S1**.

Figure 1. Simulation box and water desalination performance: (a) Angled and (b) vertical view of CHC; (c) Atom structure of the wall and junction of CHC; (d) Schematic of the simulation box consisting of a CHC, water, ions (Na^+ and Cl^-) and two graphene sheets.

NEMD simulations are employed to test the performance of CHC as water desalination membranes using the LAMMPS package [29, 30]. The post-processing including water flux, salt rejection and water molecules distribution is studied with

OVITO [31, 32]. We have used our resources to run three times for every case, and for each case, three MD simulations were performed by changing the initial conditions to achieve meaningful insights.

The interactions between the water molecules are described by the TIP4P model, and the salt ions are described by the non-polarizable model. The AIREBO potential [33] is utilized to describe the interactions between the carbon atoms. For other kinds of atoms, the Lennard Jones (LJ) and Coulombic terms are utilized [34-36]. The interaction energy $U(r_{ij})$ is given as [37]:

$$U(r_{ij}) = 4\varepsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^6 \right] + \frac{q_i q_j}{\varepsilon r_{ij}} \quad (1)$$

where ε_{ij} and σ_{ij} are the energy and length parameters, r_{ij} is the distance between the atoms i and j , q_i and q_j are the charges on the two atoms and ε is the dielectric constant. The LJ parameters between the different elements are estimated by using the Lorentz Berthelot mixing rules. The LJ parameters are summarized in Supplementary Table S1. The canonical (NVT) ensemble is used for the simulations with a Nose Hoover thermostat of 50 fs at T=300 K. The periodic boundary conditions are employed in all three directions of the simulated box, with a time step of 0.5 fs. Five different external pressures (ranging from 50 to 250 MPa) are applied on the graphene piston to achieve the water desalination process, and the pressure on the graphene piston on the fresh water side is kept at 0.1 MPa (1 atm). The simulation time is related to the applied pressure. The greater is the pressure, the shorter is the time taken by water to pass. 10,000,000 time steps are taken for each NEMD simulation.

It has been reported that the salt rejection is more important than water permeability for water desalination, which is calculated by [7]:

$$\text{Salt rejection} = \left(1 - \frac{n_{\text{Perment Ions}} / n_{\text{Ions}}}{n_{\text{Perment Water}} / n_{\text{Water}}}\right) \times 100\% \quad (2)$$

where $n_{\text{Perment Ions}}$ and $n_{\text{Perment Water}}$ represent the number of ions and water molecules which have passed through CHC when half of the water has flowed to the permeate side, whereas n_{Ions} and n_{Water} represent the number of ions and water molecules in the feed side at the beginning of the simulations.

3. Results and Discussion

3.1 Effect of pressure

Applied pressure has a significant influence on the performance of the water desalination performance of the membrane. Varying external pressures were applied to the two rigid graphene pistons in the cell axis direction so that the system is in a non-equilibrium condition with a hydrostatic pressure difference across the CHC. The number of water molecules filtered through the CHC (length $L = 5.8$ nm) pores as a function of time for different pressure values is presented in [Figure 2\(a\)](#). Each curve in [Figure 2\(a\)](#) starts in the linear state with a near constant water flow rate. This suggests that the impact of the gradually increased salinity in the feed side could be negligible in this region. The water flow rate is estimated by the slope of each curve in [Figure 2\(a\)](#). With time, the water molecules pass through CHC to the permeate side with increasing salinity in the feed side, following the osmotic gradient enhancement. Therefore, the driving force that causes the water molecules to flow is reduced, and the slope of the water molecules number vs. time curves decreases. At an externally applied pressure of 50 MPa, the water density and distribution of the oxygen atoms along the radial direction in a single pore are exhibited in [Supplementary Figure S2 and S3](#), respectively. The results show that the water

molecules are mainly distributed in the range of 1.6 to 2.4 Å from the center of the CHC pore.

Figure 2. (a) The number of the water molecules filtered through the CHC pores as a function of simulation time at different pressures and (b) Water flux and salt rejection as a function of the applied pressure for CHC.

The water flux is calculated when the half of the water molecules have entered the permeate region, using the slopes from Figure 2(a). The effective water flux values achieved in each simulation are illustrated in Figure 2(b). The results indicate that the water flux is nearly linear with the applied pressure, which is consistent with the previous studies [11].

Moreover, it has been reported that the salt rejection is more important than the water permeability for the desalination membranes [7]. The dashed line in Figure 2(b) shows the salt rejection as a function of the applied pressure. The result shows that at low pressures, CHC has a perfect salt rejection with no salt ions passing before half of the water has flowed through CHC. On increasing the applied pressure up to 150 MPa, the salt rejection reduces only to 92%. This can be explained by considering the free energy profile of an ion and water molecule passing through the CHC membrane. As expected, the higher pressure provides enough energy to the salt ions to pass through the nanoporous

1
2
3 membrane, however, at a very low extent. These results show that CHC could be an
4
5 effective water desalination membrane alternative.
6
7

8 A few previous MD studies have shown that the water flux through CNT is
9
10 affected by the length [8, 38]. In this study, the considered CHC lengths are 5.8, 11.6 and
11
12 58 nm respectively. The water flux of CHC with varying lengths as a function of applied
13
14 pressure is shown in Figure 3(a). The decay of the water flux with increasing CHC length
15
16 shows similar behaviour for different pressure values. As the length increases, the water
17
18 flux is obviously noted to decrease. For CHC with a length of 58 nm, the water flux is
19
20 noted to reduce by 17% as compared to CHC with a length of 5.8 nm at a pressure of 50
21
22 MPa. The reduction is observed to be higher on increasing the applied pressure. The
23
24 maximum reduction of water flux is noted to be about 39% at 250 MPa. It has been
25
26 reported that the use of the Nose-Hoover thermostats may overestimate the reduction in
27
28 the water flux of the nanoporous carbon materials on increasing the length [8]. Therefore,
29
30 the effective water permeability of CHC might be larger, if the similar effect occurs with
31
32 CHCs.

Figure 3. Length and temperature dependence: Water flux (a) and salt rejection (b) as a function of the applied pressure for CHCs with different lengths at different temperature conditions; (c) Water permeability of CHC at different conditions.

At 300 K, the water permeability of CHCs with different lengths is described in **Figure 3(c)**. As the CHC length increases, the water permeability decreases, exhibiting the same trend as reported for CNT for water transportation by Su [38]. Remarkably, the water permeability of CHC with a length of 58 nm is 48% lower than that of 5.8 nm. It shows the water flow through CHC is frictional [39].

The salt rejection as a function of the applied pressure is depicted in **Figure 3(b)**. Meanwhile, the membranes with CHC lengths of 11.6 nm and 58 nm length exhibit a perfect salt rejection, while the salt rejection of the CHC with 5.8 nm length is about 92% at 150 MPa. Similar salt rejection under other applied pressures is observed, indicating that the salt rejection is less affected by the CHC length.

3.2 Effect of temperature gradient

1
2
3 Increasing temperature enhances the diffusion process of both water and salt ions.
4
5 It has been reported [15] that an axial temperature gradient can induce a fast and
6
7 continuous water flow through CNT. Here, the effect of the temperature gradient on the
8
9 performance of CHC for water desalination has been investigated. Simulations under the
10
11 temperatures of 300 K and 320 K are taken as two reference groups. In order to discuss
12
13 the effect of the temperature gradient, a different thermostat for each region is considered.
14
15 The atoms in the feed and permeate sides are heated to 320 K and 300 K, respectively.
16
17 The atoms in the middle region are controlled by the microcanonical (NVE) ensemble.
18
19 This process is noted to induce the temperature gradient of 3.5 K/nm in the water
20
21 desalination system.
22
23
24
25

26 Water flux values at different temperature conditions are depicted in Figure 3 (a).
27
28 The results show that the larger water flux values are noted at 320 K than 300 K. The
29
30 kinetic energy of the water molecules increases with temperature, which makes it easy
31
32 for the water molecules to pass through. Thus, a higher water flux is noted at higher
33
34 temperatures. The large pressure gradients can induce flow in CHC, so does the
35
36 temperature gradient in this study. In order to optimally reflect the effect of temperature
37
38 gradient on the water flux, we have further considered two temperature gradients (310-
39
40 300 K and 330-300 K) at 50 MPa. The results show that the water flux increases on
41
42 increasing the temperature gradient, as shown in Supplementary Figure S4.
43
44
45
46

47 In Figure 3(c), the water permeability of CHC has been plotted. The results show
48
49 that the water permeability of CHC at 320 K is 13% higher than 300 K. The introduction
50
51 of the temperature gradient improved the water permeability of CHC by 33%, indicating
52
53 that the temperature gradient can promote the water permeability more effectively than
54
55 simply raising the temperature.
56
57
58
59
60

Previous study [40] has shown that the gases in CNT flow by applying traveling waves. Qiu et al. [41] found that the key to the water flow is the amplitude at the free end of CNT, which is induced by applying periodic force. The higher the amplitude, the greater is the water flux. Elton et al. [15] noted that the water flow in the temperature gradient direction within CNT can be caused by the difference in the amplitude of the oscillation between the high and low temperature zones. As the applied temperature gradient increases, the amplitude of the oscillations also increases, thus, causing the higher water flow rates. Here, the thermal Brownian ratchet concept [42] is also suitable for the use of CHC for water desalination. By the induced temperature gradient, the water permeability also increases obviously. The introduction of the temperature gradient, thus, promotes the flow of water in CHC.

The Soret coefficient is calculated to quantify the effect of the temperature gradient on the water flux of CHC. The Soret coefficient is defined as [16]:

$$S = D_t / D \quad (3)$$

where D_t and D are the thermal and isothermal diffusion coefficients respectively. The isothermal diffusion coefficient D is obtained from the classical mean square displacement:

$$D = \lim_{t \rightarrow \infty} \frac{1}{6Nt} \left\langle \sum_{j=1}^N |r_j(t) - r_j(0)|^2 \right\rangle \quad (4)$$

where $r(t)$ is the displacement of the atom j at time t and N is the number of atoms. The coefficient of thermal diffusion is calculated from the equation:

$$D_t = V / \Delta T \quad (5)$$

1
2
3 where V is the water flow rate determined by the water flux during the simulation. The
4
5 isothermal diffusion coefficient is $2.8 \text{ nm}^2/\text{ns}$, which is consistent with the previous
6
7 reports for water under nanoscale confinement ($0.9\text{-}8.8 \text{ nm}^2/\text{ns}$) [14, 43]. The water flux
8
9 induced by the temperature gradient under zero driving pressure is about 50 molecules/ns,
10
11 corresponding to the water flow rate of 1.16 nm/s . Thus, the extracted thermal diffusion
12
13 coefficient is $0.33 \text{ nm}^2/(\text{ns K})$, which corresponds to a Soret coefficient of 0.12 K^{-1} . The
14
15 observed value is one order of magnitude lower than the simulated coefficient for the
16
17 confined water inside CNT [14], however, it is closer to the value for the binary Lennard-
18
19 Jones liquids [44] and the experimental results for the water-methanol mixtures [16].
20
21
22

23
24 The salt rejection as a function of both temperature and applied pressure is plotted
25
26 in Figure 3(b). It is found to be 100 % for the applied pressure below 100 MPa. It is owing
27
28 to the fact that the smaller values of pressure induce smaller forces on the salt ions to pass
29
30 through CHC. The salt rejection makes a little difference at 150 MPa, where the
31
32 temperature gradient shows a 100% salt rejection, which is higher than observed for 300
33
34 K and 320 K.
35
36
37

38 *3.3 Porosity and water permeability*

39
40 The water permeability is another important factor for the water desalination
41
42 performance. Figure 4 shows the water permeability for various nanoporous carbon
43
44 materials (hydroxylated and hydrogenated graphene [10], MoS_2 , graphene [11], CNT [7]
45
46 and graphyne [9]) including CHC with $L = 5.8 \text{ nm}$ calculated in this study. CHC shows a
47
48 better water permeability performance than the 2D membranes of graphene, MoS_2 ,
49
50 graphene with hydroxylated or hydrogenated pores and graphyne-5, with similar pore
51
52 area. For 2D nanoporous materials, the pores tend to weaken the material by reducing its
53
54 structural strength. It was reported that both strength and Young's modulus of the
55
56 nanoporous graphene reduce on increasing the pore radius [3]. It is important for a
57
58
59
60

material to be strong in order to maintain its mechanical structure under high hydraulic pressure inherent to the reverse osmosis desalination process. Thus, the porosity of such materials is generally small. This, thus, greatly limits water permeability of these materials. For instance, the water permeability of graphene with a 10% porosity is about 1000 L/(m²·h·Bar) [10].

Figure4. The performance of various membranes with similar single area for water desalination at 300 K. The single pore area of CHC is 78 Å² with L = 5.8 nm. The pore area of the hydroxylated and hydrogenated graphene [10], MoS₂ and graphene [11] is 62, 50, 56 and 60 Å² respectively, and the corresponding permeability is calculated assuming a 10% porosity. The pore area of CNT (12,12) [7] and Graphyne-5 [45] is 62 and 77 Å².

However, it is generally less critical to focus on the strength of CHC due to its unique nanoporous structure. The stress-strain curves along different directions show that CHC has outstanding structural strength (as shown in [Supplementary Figure S5](#)). In this study, CHC has a nanopore density of 1.15×10^{14} cm⁻², while it is 1.7×10^{13} cm⁻² for graphene [3], 7.9×10^{13} cm⁻² for graphyne-5 [9] and only 2.5×10^{11} cm⁻² for CNT [7] with similar pore area. For simplicity, the porosity is expressed by the ratio of the hole area and total cross-sectional area, where the hole area is calculated by the area of the inscribed circle of the hole. The calculated porosity of CHC is noted to be about 64%, whereas it is 43% for graphyne-5, 10% for graphene and only 0.5% for CNT.

Benefitting from the specific structure, the CHC membrane has a relatively high porosity, while maintaining a high stiffness. Therefore, CHC is noted to have a higher

1
2
3 water permeability as compared to other materials. It has been reported that with a
4
5 thickness of 3 nm and a diameter of 1.6 nm, CNT has a water permeability about 160
6
7 $L/(m^2 \cdot h \cdot bar)$ [7], which is more than one order of magnitude lower than CHC with similar
8
9 pore area.
10
11
12

13 14 **4. Conclusions**

15
16 A promising performance of CHC for water desalination has been predicted by
17
18 means of molecular dynamics simulations. Benefitting from the specific structure of an
19
20 array of honeycomb holes, the CHC membrane is noted to possess a relatively high
21
22 porosity with high stiffness. To the authors' best knowledge, the water permeability of
23
24 CHC is greater than other carbon materials and reverse osmosis membranes. The water
25
26 transport through CHC is pressure dependent. Besides, the water permeability of CHC
27
28 increased by inducing the temperature gradient, thus, providing a promising approach to
29
30 improve the water flux. CHC shows high salt rejection for the applied pressure of less
31
32 than 150 MPa. Overall, the newly developed CHC based water desalination membrane
33
34 exhibits strong potential for seawater desalination and water transportation, along with
35
36 application to the nanofluidic devices.
